## Abstract

The broadcast nature of the wireless medium makes the communication over this medium vulnerable to eavesdropping. This report considers the problem of secret communication between two nodes, over a fading wireless medium, in the presence of a passive eavesdropper. The assumption used is that the transmitter and its helpers (amplifying relays) have more antennas than the eavesdropper. The transmitter ensures secrecy of communication by utilizing some of the available power to produce ‘artificial noise’, such that only the eavesdropper’s channel is degraded. Two scenarios are considered, one where the transmitter has multiple transmit antennas, and the other where amplifying relays simulate the effect of multiple antennas. The channel state information (CSI) is assumed to be publicly known, and hence, the secrecy of communication is independent of the secrecy of CSI.

# Chapter 1

## Introduction

### 1.1 Secrecy Problem in a Wireless Environment

The broadcast nature of the wireless medium makes wireless networks easily accessible. Advances in wireless communication technology has made it possible to stay connected to the network anywhere, anytime. However, this ease of accessibility also makes it easy to overhear communication over this medium, thus raising privacy concerns. Secrecy problems involve three nodes; transmitter, receiver and an eavesdropper. We consider the problem of secret communication, over a wireless medium, where the transmitter wants to transmit a secret message to the intended receiver, such that the eavesdropper is unable to decode it. The eavesdropper is assumed to be passive and hence, its location, and even its presence will be uncertain to the transmitter. Thus, in the presence of passive eavesdroppers, secrecy must be guaranteed regardless of the eavesdropper's position.

### 1.2 Background

Claude Shannon laid the theoretical foundation for the study of secret communication [1]. He showed that perfect secrecy is achievable only if the secret key is at least as large as the secret message. However, this pessimistic result was based on the assumption that the eavesdropper has access to precisely the same information as the receiver, except the secret key. Later, [2] considered a scenario where the receiver and the eavesdropper have separate channels, and showed that secret

communication is possible if the eavesdropper's channel has a smaller capacity than the receiver's channel. The paper generalized the scenario considered in [3] where the eavesdropper's channel was a degraded version of the receiver's channel; and hence, the former was guaranteed to be worse than the latter. The paper also defined the notion of 'secrecy capacity', which essentially is the maximum rate at which the transmitter can reliably communicate a secret message to the intended receiver, without the eavesdropper being able to decode it. However, if the eavesdropper happens to have a better channel than the receiver (e.g., if the eavesdropper is closer to the transmitter, versus the receiver), then the secrecy capacity is zero, meaning that secrecy could not be guaranteed for an arbitrary location of the eavesdropper. [7] presented a solution to this problem, where the transmitter can use some of the available power to transmit artificially generated noise. Since, this noise is generated by the transmitter, the transmitter can design it such that only the eavesdropper's channel is degraded. Thus, by selectively degrading the eavesdropper's channel, the eavesdropper's channel can be made worse than the receiver's channel, and secret communication can be guaranteed, based on the result in [2].

Two schemes for generating artificial noise were introduced in [5]. In the first scheme, the transmitter can use multiple transmit antennas to generate 'artificial noise'. This scenario was chosen because the artificial noise scheme can be presented in a simple manner, in this case. This scenario models a base station wanting to communicate a secret message to a mobile handset. In the second scheme, it was shown that even if the transmitter does not have multiple transmit antennas but 'amplifying relays' [20] (or 'helper nodes') are present, the effect of multiple antennas can be simulated and artificial noise can still be produced. This scenario models a mobile handset, with a single antenna, wanting to communicate a secret message to another mobile handset or the base station. The multiple antenna scheme was further analyzed in [6]. The paper explored the notion of 'MIMO secrecy capacity' and showed that it behaves differently from MIMO capacity, showing that the secrecy requirement changes the behavior of MIMO capacity. For example, the paper showed that secrecy capacity does not increase monotonically with the minimum of the number of transmit and receive antennas, unlike the celebrated result on usual MIMO capacity [8]. Thus, the paper highlighted the need to characterize MIMO secrecy capacity. The paper further showed that with the use of artificial noise, a certain minimum rate of secret transmission can be guaranteed, regardless of the eavesdropper's position. Both of these papers assessed the artificial noise schemes

through Monte Carlo simulations. [7] presented results on the *minimum guaranteed secrecy capacity*, which is defined as the minimum secrecy capacity, that can be guaranteed regardless of the eavesdropper's position, assuming a fading channel model. This required a modification of the schemes analyzed in [5] and [6] to ensure non-zero minimum guaranteed secrecy capacity. The paper presented analytical results in addition to simulation results.

Note that the result in [2], and consequently, this report, considers information theoretic secrecy which is provably secure, as opposed to classical symmetric encryption schemes [4]. Information theoretic secrecy does not assume that a secure key exchange has occurred between the transmitter and the receiver, as is assumed in the classical symmetric encryption schemes. On the other hand, the secrecy rates guaranteed by the information theoretic results might be substantially smaller than those achievable through symmetric encryption schemes. Thus, information theoretic schemes can be used in conjunction with the classical schemes, by generating keys which can then be used to perform symmetric encryption. However, practical codes are not known which can achieve the rates guaranteed by information theoretic results on secrecy.

### 1.3 Related Work

In related work, [9] presented a technique for introducing ambiguity in the eavesdropper's channel, using multiple transmit antennas. However, secrecy capacity obtained using this scheme was not analyzed. [10] described a technique for secret communication where the channel state information (CSI) was used as the secret key. In particular, the phase information was used as a secret key and the transmitter compensated for the phase before transmission. The phase of the eavesdropper's channel, being different from that of the receiver's channel, in general, prevented the eavesdropper from decoding the secret message. [11] generalized this technique for the multi-antenna scenario. [12] obtained an abstract characterization of secrecy capacity of the kind discussed in [10]. In contrast, this paper assumes that the CSI is publicly known, and thus, it cannot be used to obtain a secret key. The secrecy of the schemes discussed in this paper is independent of the secrecy of the CSI. However, in this paper, we make the (admittedly strong) assumption that the number of eavesdropper antennas is strictly smaller than the number of transmitter (along with amplifying relays) antennas. This assumption may be valid in certain scenarios, such as a powerful base station

deploying several antennas, serving as a transmitter. [13] analyzed secrecy capacity for slow fading wireless channels, but without the use of artificial noise. This report shows that much lower outage probabilities can be guaranteed using artificial noise.

## 1.4 Outline

This report is organized as follows. Chapter 2 formulates the secrecy problem considered in this report. It introduces the two scenarios considered in this report, one with multiple antennas at the transmitter, and the other with amplifying relays. Chapter 3 introduces the scheme for artificial noise generation, using multiple transmit antennas. This chapter assumes that both the receiver and the eavesdropper have a single antenna each. Chapter 4 presents the scheme for artificial noise generation, when all the nodes have a single antenna each. This chapter shows how the effect of multiple transmit antennas can be reproduced with the help of amplifying relays. Chapter 5 characterizes the behavior of MIMO secrecy capacity. It also presents analytic results on the minimum guaranteed average secrecy capacity, in the regime of large number of antennas. Chapter 6 presents simulation results that characterize secrecy capacity obtained using the two different schemes. Chapter 7 concludes the report.

## Chapter 2

# Problem Scenario

### 2.1 Introduction

In this report, we consider the problem of guaranteeing secret communication, in a wireless medium, in the presence of a passive eavesdropper. The key idea in this report is that it is possible to selectively degrade the eavesdropper's channel, regardless of its position, so that its channel is worse than the receiver's channel. This can be achieved by utilizing the multipath nature of the wireless channel which results in independent fading channels for the receiver and the eavesdropper. Since fading for the different channels is independent, the transmitter can design a signal, such that it only cancels out at the receiver, and not at the eavesdropper. This signal can be used as an *artificial* noise signal, which will selectively degrade the eavesdropper's channel. The transmitter can use some of the available power to transmit this artificially generated noise, so that eavesdropper's channel can be made worse than the receiver's channel, and secret communication can be guaranteed. This report considers two scenarios, which demonstrate different methods of generating artificial noise. In the first scenario, the transmitter can use the degrees of freedom provided by multiple transmit antennas, to generate artificial noise. In the second scenario, the transmitter has only a single transmit antenna. However, it can coordinate with amplifying relays, to produce the effect of multiple transmit antennas. In this scenario, we assume that transmissions of all nodes are synchronized (which is clearly an idealistic assumption).

We denote vectors and matrices with bold font.  $\dagger$  is used to denote the Hermitian operator.

For convenience, we measure information in nats instead of bits (i.e.,  $\log_e(\cdot)$  is used to calculate entropy). We first consider the simpler Scenario 1.

## 2.2 Multiple Antennas: Scenario 1

Scenario 1 in Fig. 2.1 shows transmitter  $A$  with  $N_T$  antennas, receiver  $B$  with  $N_R$  antennas and an eavesdropper  $E$  with  $N_E$  antennas. An eavesdropper with multiple antennas is an abstraction of the case where, a) either the eavesdropper has multiple receive antennas or b) several eavesdroppers (with perhaps one antenna each) collude. The latter case of collusion can be modeled as a single eavesdropper with multiple antennas, if we assume that their received signals can be processed by a central node. Clearly, this form of collusion represents the worst case scenario in terms of secrecy capacity, given a fixed number of colluding eavesdroppers.  $\mathbf{H}_k$  and  $\mathbf{G}_k$  denote the channels of the receiver and the eavesdropper respectively, at time  $k$ .  $A$  transmits  $\mathbf{x}_k$  at time  $k$ .  $B$  and  $E$  receive, respectively,

$$\mathbf{z}_k = \mathbf{H}_k \mathbf{x}_k + \mathbf{n}_k, \quad (2.1)$$

$$\mathbf{y}_k = \mathbf{G}_k \mathbf{x}_k + \mathbf{e}_k, \quad (2.2)$$

where the components of  $\mathbf{n}_k$  and  $\mathbf{e}_k$  are i.i.d. Additive White Gaussian Noise (AWGN) samples with variance  $\sigma_n^2$  and  $\sigma_e^2$ , respectively. Block fading is assumed, meaning that  $\mathbf{H}_k$  and  $\mathbf{G}_k$  are constant over a block of large number of symbols so that information theoretic results can be applied within each block and  $\mathbf{H}_k$ ,  $\mathbf{G}_k$  in different blocks are independent. Thus, encoding and decoding is performed independently for each fading block. A more general fading channel could be used, but the resulting analysis will be much more complicated [21]. The elements of  $\mathbf{H}_k$  and  $\mathbf{G}_k$  are assumed to be complex numbers, i.i.d. and independent of each other. This would occur under ‘rich scattering’ [14]. It is assumed that the receiver is able to estimate its channel  $\mathbf{H}_k$  perfectly and feed it back to the transmitter noiselessly. Further, we assume that the transmitter can *authenticate* the fed back channel gain, perhaps using some shared initial key. The eavesdropper is assumed to be passive, which means that the eavesdropper only listens but does not transmit. Hence, the transmitter may not know the eavesdropper’s channel  $\mathbf{G}_k$ . However, it is assumed that the eavesdropper may know both the receiver’s and its own channel. Note that *the secrecy of this scheme is not dependent on the secrecy of the channel gains*. The transmitter is assumed

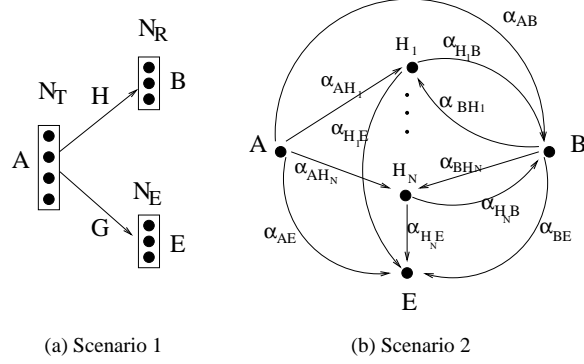

Figure 2.1: Framework for secrecy capacity

to have a power constraint of  $P_0$ , i.e.,  $\mathbf{E}[\mathbf{x}_k^\dagger \mathbf{x}_k] \leq P_0$ . The secrecy condition is defined in terms of equivocation rate. Let the secret message  $m^K \doteq (m_1, \dots, m_K)$  be encoded into  $\mathbf{x}^N$ .  $\mathbf{z}^N$  and  $\mathbf{y}^N$  are then obtained following (2.1), (2.2). The rate of transmission between the transmitter and the receiver is  $R = H(m^K)/N$ . The equivocation rate is defined as  $R_e \doteq \frac{1}{K} H(m^K | \mathbf{y}^N)$ . Perfect secrecy is achieved (as defined in [2]) if  $R_e = R$ . Note that this secrecy condition restricts the rate at which the eavesdropper can obtain the secret information. A stricter secrecy condition can be used which restricts the total amount of secret information obtained by the eavesdropper, using the techniques introduced in [19]. The same secrecy condition is used in the next scenario as well.

### 2.3 Multiple Amplifying Relays: Scenario 2

In the previous scenario, the transmitter can utilize its multiple transmit antennas for secret transmission. The second scenario considers the case where the transmitter does not have multiple transmit antennas, but instead, has amplifying relays for cooperation. Henceforth, in this paper, we will refer to them as relays. Scenario 2 in Fig. 2.1 shows transmitter  $A$ , intended receiver  $B$  and an eavesdropper  $E$  with only a single antenna each. But several relays ( $H_1, H_2, \dots, H_N$ ) exist to aid secret communication from  $A$  to  $B$ . The multiple relays must simulate the effect of having multiple transmit antennas. However, unlike Scenario 1, the transmitter cannot directly control the signal transmitted by the relays. The channel gain from  $X$  to  $Y$  is denoted  $\alpha_{XY}$ , which models a fading channel. Note that the channels are not necessarily reciprocal, i.e., in general  $\alpha_{XY} \neq \alpha_{YX}$ . A flat fading channel model is assumed, similar to (2.1), (2.2). Again, it is assumed that the channels

gains remain constant over a large number of symbols, so that information theoretic results can be applied within each fading block. The transmission of secret information from the transmitter to the receiver occurs in two stages which will be discussed in detail in a later chapter. It is assumed that all the channel gains are known to all the nodes (possibly, even to the eavesdropper). Again, the secrecy of our communication scheme does not depend on the secrecy of channel gains. We assume that the total power transmitted by all the nodes for both the stages (including nodes  $A$ ,  $B$  and the relays), is constrained to  $P_0$ . The exact form of the power constraint will be specified later.

## Chapter 3

# Artificial Noise using Multiple Transmit Antennas

### 3.1 Introduction

In this chapter, we consider the first scenario (Scenario 1). To introduce our scheme, this chapter assumes that both the receiver and the eavesdropper have a single antenna each, and that multiple eavesdroppers cannot collude (i.e.,  $N_R = N_E = 1$ ). An example of such a scenario is a wireless LAN, with the base station as the transmitter. The concept of artificial noise can be clearly illustrated in this scenario. The artificial noise is produced such that it lies in the null space of the receiver's channel, while the information signal is transmitted in the range space of the receiver's channel. This design relies on knowledge of the receiver's channel, but not of the eavesdropper's channel. The receiver's channel nulls out the artificial noise and hence, the receiver remains unaffected by the noise. However, in general, the eavesdropper's channel will be degraded, since its range space will be different from that of the receiver's channel, and hence, some component of artificial noise will lie in its range space.

## 3.2 Artificial Noise Generation

We now describe how the transmitter can generate artificial noise to degrade the eavesdropper's channel. The transmitter chooses  $\mathbf{x}_k$  as the sum of information bearing signal  $\mathbf{s}_k$  and the artificial noise signal  $\mathbf{w}_k$ ,

$$\mathbf{x}_k = \mathbf{s}_k + \mathbf{w}_k. \quad (3.1)$$

Both  $\mathbf{s}_k$  and  $\mathbf{w}_k$  are assumed complex Gaussian vectors.  $\mathbf{w}_k$  is chosen to lie in the null space of  $\mathbf{H}_k$ , such that  $\mathbf{H}_k \mathbf{w}_k = \mathbf{0}$ . If  $\mathbf{Z}_k$  is an orthonormal basis for the null space of  $\mathbf{H}_k$ , then  $\mathbf{w}_k = \mathbf{Z}_k \mathbf{v}_k$ , and  $\mathbf{Z}_k^\dagger \mathbf{Z}_k = I$ . Then, the signals received by the receiver and the eavesdropper are given by, respectively,

$$z_k = \mathbf{H}_k \mathbf{s}_k + n_k, \quad (3.2)$$

$$y_k = \mathbf{G}_k \mathbf{s}_k + \mathbf{G}_k \mathbf{w}_k + e_k. \quad (3.3)$$

Note how the artificial noise  $\mathbf{w}_k$  is nulled out by the receiver's channel but not necessarily by the eavesdropper's channel. Thus, the eavesdropper's channel is degraded with high probability, while that of the receiver remains unaffected. If  $\mathbf{w}_k$  was chosen fixed, the artificial noise seen by the eavesdropper would be small if  $\|\mathbf{G}_k \mathbf{w}_k\|$  turned out to be small. To avoid this possibility, the sequence of  $\mathbf{w}_k$  is chosen to be complex Gaussian random vectors in the null space of  $\mathbf{H}_k$ . In particular, the transmitter chooses elements of  $\mathbf{v}_k$  to be i.i.d. complex Gaussian *random* variables with variance  $\sigma_v^2$ , and independent in time as well. It follows that the elements of  $\mathbf{w}_k$  are also Gaussian distributed.

## 3.3 Secrecy Capacity

Since  $\mathbf{H}_k$  is a vector channel, the transmitter chooses the information bearing signal as  $\mathbf{s}_k = \mathbf{p}_k u_k$ , where  $u_k$  is the information signal. We assume that Gaussian codes are used.  $\mathbf{p}_k$  is chosen such that  $\mathbf{H}_k \mathbf{p}_k \neq 0$  and  $\|\mathbf{p}_k\| = 1$ . Now, secrecy capacity is bounded below by the difference in mutual information between the transmitter and the receiver versus the transmitter and the eavesdropper

[2, 15],

$$\text{Secrecy Capacity} \geq C_{sec}^a = I(Z; U) - I(Y; U) \quad (3.4)$$

$$= \log\left(1 + \frac{|\mathbf{H}_k \mathbf{p}_k|^2 \sigma_u^2}{\sigma_n^2}\right) - \log\left(1 + \frac{|\mathbf{G}_k \mathbf{p}_k|^2 \sigma_u^2}{\mathbf{E}|\mathbf{G}_k \mathbf{w}_k|^2 + \sigma_e^2}\right), \quad (3.5)$$

where  $\mathbf{E}|\mathbf{G}_k \mathbf{w}_k|^2 = (\mathbf{G}_k \mathbf{Z}_k \mathbf{Z}_k^\dagger \mathbf{G}_k^\dagger) \sigma_v^2$ . For a passive eavesdropper,  $\mathbf{G}_k$  is not known to the transmitter, so using the concavity of  $\log(\cdot)$  and the i.i.d. assumption of  $\mathbf{G}_k$ , the average secrecy capacity is maximized by choosing  $\mathbf{p}_k = \mathbf{H}_k^\dagger / \|\mathbf{H}_k\|$ . Thus, the information bearing signal  $\mathbf{s}_k$  lies in the range space of  $\mathbf{H}_k^\dagger$  whereas the artificial noise is transmitted in the null space of  $\mathbf{H}_k^\dagger$ .

$C_{sec}^a$  is a random variable because it is a function of random channel gains  $\mathbf{H}_k$  and  $\mathbf{G}_k$ . Therefore, we study average secrecy capacity and outage probability (or outage capacity). We assume that the total transmit power, given by  $f_1(\sigma_u^2, \sigma_v^2) = \mathbf{E}[\mathbf{x}_k^\dagger \mathbf{x}_k] \leq P_0 = \sigma_u^2 + (N_T - 1)\sigma_v^2$ , is constrained to  $P_0$ . Now,  $\sigma_u^2, \sigma_v^2$  can be chosen to maximize the lower bound on average secrecy capacity,

$$\overline{C_{sec}^a} \doteq \max_{f_1(\sigma_u^2, \sigma_v^2) \leq P_0} \mathbf{E}_{\mathbf{H}_k, \mathbf{G}_k} \left[ \log\left(1 + \frac{\|\mathbf{H}_k\|^2 \sigma_u^2}{\sigma_n^2}\right) - \log\left(1 + \frac{|\mathbf{G}_k \mathbf{p}_k|^2 \sigma_u^2}{(\mathbf{G}_k \mathbf{Z}_k \mathbf{Z}_k^\dagger \mathbf{G}_k^\dagger) \sigma_v^2 + \sigma_e^2}\right) \right]. \quad (3.6)$$

Note that the definition of  $\overline{C_{sec}^a}$  involves both the expectation over  $\mathbf{H}_k, \mathbf{G}_k$ , and the optimization over  $\sigma_u^2, \sigma_v^2$ . Similar notation will be used in the later chapters to denote maximum average secrecy capacity.  $\overline{C_{sec}^a}$  depends on the AWGN power seen by the eavesdropper  $\sigma_e^2$ , which depends on the position of the eavesdropper. The worst case situation would occur if  $\sigma_e^2 \rightarrow 0$  (e.g., when the eavesdropper is much closer to the transmitter, compared to the receiver). The secrecy capacity obtained in this scenario will be the minimum secrecy capacity that can be guaranteed, irrespective of the eavesdropper's position, given by,

$$\overline{C_{sec}^a} \geq \overline{C_{sec,mg}^a} \doteq \max_{f_1(\sigma_u^2, \sigma_v^2) \leq P_0} \mathbf{E}_{\mathbf{H}_k, \mathbf{G}_k} \left[ \log\left(1 + \frac{\|\mathbf{H}_k\|^2 \sigma_u^2}{\sigma_n^2}\right) - \log\left(1 + \frac{|\mathbf{G}_k \mathbf{p}_k|^2 \sigma_u^2}{(\mathbf{G}_k \mathbf{Z}_k \mathbf{Z}_k^\dagger \mathbf{G}_k^\dagger) \sigma_v^2}\right) \right]. \quad (3.7)$$

### 3.4 Asymptotic Analysis

Note that the minimum guaranteed average secrecy capacity can be positive, even as  $\sigma_e^2 \rightarrow 0$ , unlike the case where artificial noise is not used (i.e., if only the information bearing signal is transmitted). To see this, consider a specific choice for signal and artificial noise powers,  $\sigma_u^2 = \theta P_0$  and  $\sigma_v^2 = (1 - \theta)P_0 / (N_T - 1)$ , for some fixed  $\theta$ . Now, the second term in (3.7) is a constant, while the first term tends to infinity, as  $P_0 \rightarrow \infty$ . Thus,  $\overline{C_{sec,mg}^a} \rightarrow \infty$ , as  $P_0 \rightarrow \infty$  which shows

that  $\overline{C_{sec,mg}^a}$  is non-zero for large enough  $P_0$ . Further, as  $\sigma_e^2 \rightarrow \infty$  (e.g., when the eavesdropper is much farther from the transmitter, than is the receiver), the second term in (3.6) goes to zero, for any choice of  $\sigma_u^2, \sigma_v^2$ . Now,  $\overline{C_{sec}^a}$  can be maximized by choosing  $\sigma_u^2 = P_0$ , hence obtaining average capacity as the average minimum guaranteed secrecy capacity. Fig. 6.1 shows that  $\overline{C_{sec}^a}$  achieves capacity when  $\sigma_e^2 \rightarrow \infty$ , while  $\overline{C_{sec}^a}$  achieves a non-zero  $\overline{C_{sec,mg}^a}$  when  $\sigma_e^2 \rightarrow 0$ .

## Chapter 4

# Artificial Noise in Multiple Amplifying Relays Scenario

### 4.1 Introduction

In Chapter 3, we saw that multiple antennas at the transmitter can be used to produce artificial noise. We now consider the case when the transmitter has only a single antenna. The method used in the previous chapter can no longer be used here. However, we assume that several relays are present to aid the secret transmission of information. Coordination with the relays can, hopefully, simulate the effect of multiple antennas in producing artificial noise. However, as opposed to the case of multiple transmit antennas, the relays are not in direct control of the transmitter. How can they then coordinate in transmitting the artificial noise (which, by definition, is random and cannot be known to the relays)? We now describe a novel 2-stage protocol that achieves this coordination.

### 4.2 Artificial Noise Generation

In the first stage, the transmitter and the intended receiver both transmit independent artificial noise signals to the relays. The relays and the eavesdropper receive different linear combinations of these two signals. In the second stage, the relays simply replay a weighted version of the received signal, using a publicly available sequence of weights (i.e., weights that may also be known to the

eavesdropper). At the same time, in this second stage, the transmitter transmits its secret message, along with a weighted version of its artificial noise, which was transmitted in the first stage. The weighted version is generated such that the artificial noise component due to the transmitter is canceled at the receiver. The artificial noise component due to the receiver is anyway known to the receiver, and can be canceled off by the receiver. The two stages are now described in detail.

**Stage 1:**  $A$  and  $B$  transmit  $\alpha_{AB} x$  and  $y$  respectively.  $H_i$  and  $E$  receive, respectively,

$$r_{H_i} = \alpha_{AH_i} \alpha_{AB} x + \alpha_{BH_i} y + n_i \quad (4.1)$$

$$r_{E,1} = \alpha_{AE} \alpha_{AB} x + \alpha_{BE} y + e_1 \quad (4.2)$$

**Stage 2:**  $A$  and  $H_i$  transmit  $-\sum_i \beta_i \alpha_{AH_i} \alpha_{H_i B} x + z$  and  $\beta_i r_{H_i}$  respectively.  $B$  and  $E$  receive,

$$r_B = \alpha_{AB} z + \sum_i \beta_i \alpha_{BH_i} \alpha_{H_i B} y + \sum_i \beta_i \alpha_{H_i B} n_i + n_0 \quad (4.3)$$

$$\begin{aligned} r_{E,2} = & \alpha_{AE} z + [\alpha_{AB} \sum_i \beta_i \alpha_{AH_i} \alpha_{H_i E} - \alpha_{AE} \sum_i \beta_i \alpha_{AH_i} \alpha_{H_i B}] x + \\ & \sum_i \beta_i \alpha_{BH_i} \alpha_{H_i E} y + \sum_i \beta_i \alpha_{H_i E} n_i + e_2 \end{aligned} \quad (4.4)$$

Here,  $\{e_i\}_{i=1}^2$ ,  $\{n_i\}_{i=0}^N$  are AWGN noise samples of variance  $\sigma_e^2$  and  $\sigma_n^2$  respectively.  $\beta_i$  are i.i.d. complex Gaussian random weights used by the relays (known publicly).  $z$  is the Gaussian information bearing signal which must be communicated by  $A$  to  $B$ , while  $x$  and  $y$  are transmitted to conceal the transmission of  $z$ . Note that  $y$  is known to the receiver, and hence, it can be easily canceled off by the receiver. Thus, the equivalent channel from  $A$  to  $B$  is given by

$$\tilde{r}_B = \alpha_{AB} z + n_B, \quad (4.5)$$

where  $n_B = \sum_{i=1}^{N_H} \beta_i \alpha_{H_i B} n_i + n_0$ . Note how  $A$ 's transmission of  $-\sum_{i=1}^{N_H} \beta_i \alpha_{AH_i} \alpha_{H_i B} x$  cancels out the transmission of the relays precisely, only at the intended receiver, but not at the eavesdropper, thus causing artificial noise in the latter. Thus, the coordination with the relays enabled the transmitter to generate artificial noise, such that it degrades only the eavesdropper's channel. Varying the  $\beta_i$  performs the same function as varying  $\mathbf{w}_k$  in Scenario 1, and thus, reduces the probability of the artificial noise being nulled at the eavesdropper. The channel from  $A$  to  $E$  can

be written as,

$$\mathbf{r}_E = \mathbf{h}_z z + \mathbf{H}_{xy} \begin{pmatrix} x \\ y \end{pmatrix} + \mathbf{n}, \quad (4.6)$$

$$\mathbf{h}_z = \begin{pmatrix} 0 \\ \alpha_{AE} \end{pmatrix}, \mathbf{n} = \begin{pmatrix} e_1 \\ \sum_{i=1}^{N_H} \beta_i \alpha_{H_i E} n_i + e_2 \end{pmatrix}, \mathbf{H}_{xy} = \begin{pmatrix} \alpha_{AB} & \alpha_{AE} & & \alpha_{BE} \\ & \gamma & & \sum_{i=1}^{N_H} \beta_i \alpha_{BH_i} \alpha_{H_i E} \end{pmatrix}, \quad (4.7)$$

where  $\gamma = \alpha_{AB} \sum_{i=1}^{N_H} \beta_i \alpha_{AH_i} \alpha_{H_i E} - \alpha_{AE} \sum_{i=1}^{N_H} \beta_i \alpha_{AH_i} \alpha_{H_i B}$ . Note that (4.5), (4.6) are similar to the ones obtained for the multiple antenna scenario (3.2), (3.3).

### 4.3 Secrecy Capacity

Eq. (4.6) represents a Single Input Multiple Output (SIMO) channel which is degraded by both AWGN and interference, and its capacity is given by [16],

$$C = \log |\mathbf{h}_z \mathbf{h}_z^\dagger \sigma_z^2 + \mathbf{K}| - \log |\mathbf{K}|, \quad (4.8)$$

$$\mathbf{K} = \begin{pmatrix} |h_{11}|^2 \sigma_x^2 + |h_{12}|^2 \sigma_y^2 + \sigma_e^2 & 0 \\ 0 & \mathbf{E}[|h_{21}|^2] \sigma_x^2 + \mathbf{E}[|h_{22}|^2] \sigma_y^2 + \sum_{i=1}^{N_H} (|\alpha_{H_i E}|^2 \sigma_{\beta_i}^2) \sigma_n^2 + \sigma_e^2 \end{pmatrix} \quad (4.9)$$

where  $h_{11}, h_{12}, h_{21}, h_{22}$  are the elements of  $\mathbf{H}_{xy}$ . Note that the off-diagonal elements of  $\mathbf{K}$  are zero, because  $\beta_i$ 's are assumed complex Gaussian. Thus, the lower bound on secrecy capacity is given by,

$$C_{sec}^h = I(Z; \tilde{R}_B) - I(Z; R_{E,1}, R_{E,2}) = \log(1 + |\alpha_{AB}|^2 \sigma_z^2 / \sigma_{n_B}^2) - \log |\mathbf{h}_z \mathbf{h}_z^\dagger \sigma_z^2 + \mathbf{K}| / |\mathbf{K}|, \quad (4.10)$$

where  $\sigma_{n_B}^2 = \sum_{i=1}^{N_H} (|\alpha_{H_i B}|^2 \sigma_{\beta_i}^2) \sigma_n^2 + \sigma_e^2$ . Note the similarity in expressions in (3.5) and (4.10).

$C_{sec}^h$  is a random variable because it is a function of random channel gains. The (average) total power, transmitted by all nodes, in the two stages, is given by  $f_2(\sigma_x^2, \sigma_y^2, \sigma_z^2, \xi) = (2N_H \xi + 1) \sigma_x^2 + (N_H \xi + 1) \sigma_y^2 + \sigma_z^2 + N_H \xi$ , where we choose  $\sigma_{\beta_i}^2 = \xi \quad \forall i$  for simplicity. Further, it is assumed that  $\mathbf{E}[|\alpha_{XY}|^2] = 1$ . The combination of powers  $(\sigma_x^2, \sigma_y^2, \sigma_z^2, \xi)$  is chosen to maximize the average  $C_{sec}^h$  and hence,

$$\overline{C_{sec}^h} \doteq \max_{f_2(\sigma_x^2, \sigma_y^2, \sigma_z^2, \xi) \leq P_0} \mathbf{E}[\log(1 + |\alpha_{AB}|^2 \sigma_z^2 / \sigma_{n_B}^2) - \log |\mathbf{h}_z \mathbf{h}_z^\dagger \sigma_z^2 + \mathbf{K}| / |\mathbf{K}|], \quad (4.11)$$

where the expectation is over all the channel gains. Note that the *total* transmit power (including transmit power of relays) is constrained to  $P_0$ .

## 4.4 Asymptotic Analysis

Again, secrecy capacity depends on the AWGN power seen by the eavesdropper  $\sigma_e^2$ . The minimum guaranteed average secrecy capacity,  $\overline{C_{sec,mg}^h}$  can be obtained by putting  $\sigma_e^2 = 0$ . It is clear that by choosing the specific values,  $\sigma_z^2 = \theta_0 P_0$ ,  $\sigma_x^2 = \theta_1 P_0$ ,  $\sigma_y^2 = \theta_2 P_0$  (where  $\theta_0, \theta_1, \theta_2 > 0$  and satisfy the power constraint), putting  $\sigma_e^2 = 0$ , and letting  $P_0 \rightarrow \infty$ , the second term in (4.11) is a constant, while the first term goes to infinity. Therefore,  $\overline{C_{sec,mg}^h} \rightarrow \infty$ , as  $P_0 \rightarrow \infty$ . Further, as  $\sigma_e^2 \rightarrow \infty$ , the second term in (4.11) goes to zero. In that case, the first term can be maximized by choosing  $\sigma_{\beta_i}^2 = 0$  and setting  $\sigma_z^2 = P_0$ , thus achieving average capacity of the transmitter-receiver link as the minimum guaranteed average secrecy capacity. Fig. 6.2 shows that  $\overline{C_{sec}^h}$  achieves the usual Shannon capacity when  $\sigma_e^2 \rightarrow \infty$ , while  $\overline{C_{sec}^h}$  achieves a non-zero  $\overline{C_{sec,mg}^h}$  when  $\sigma_e^2 \rightarrow 0$ .

## Chapter 5

# Artificial Noise in MIMO Scenario

### 5.1 Introduction

In the previous two chapters, we presented methods for artificial noise generation, both using multiple transmit antennas and relays, assuming a single-antenna eavesdropper. It was shown that in both the scenarios, some minimum secrecy capacity can be guaranteed, using artificial noise, so long as the transmitter, along with relays, has more than one antenna. We now consider an extension of the multiple antenna scenario where all the nodes, including the eavesdropper, can have multiple antennas. In recent years, several results have characterized the capacity of such Multiple Input Multiple Output (MIMO) communication systems, showing a linear increase in capacity with the minimum of the number of transmit and receive antennas [8]. In this chapter, we characterize the *minimum guaranteed* ‘MIMO secrecy capacity’, and show that it does not necessarily grow linearly with the minimum of the number of transmit and receive antennas, and thus behaves differently from the usual MIMO capacity.

Consider the case where  $N_R = N_E$ , i.e., both the receiver and the eavesdropper have similar capabilities. An increase in the number of receive antennas affects two aspects of secrecy capacity; the ability to utilize ‘parallel channels’ and the ability to produce artificial noise. Intuitively, the more the number of receive antennas, more the number of parallel channels that can be created between the transmitter and the receiver, leading to capacity gain. On the other hand, more receive antennas (and thus, more eavesdropper antennas) requires artificial noise to be produced in

more dimensions (artificial noise is produced in at least  $N_E$  dimensions), thus limiting the number of dimensions available for information transmission. These two opposing effects suggest that the effect of increasing  $N_R (= N_E)$  on MIMO secrecy capacity is not obvious. [6] investigated the notion of MIMO secrecy capacity and showed that its behavior differs from that of capacity. However, [6] considered the case when the eavesdropper's channel is degraded with AWGN. We now consider the worst case scenario, where the eavesdropper's channel has no AWGN, and hence characterize the minimum guaranteed secrecy capacity. The transmission strategy needs to be modified compared to [6], in order to obtain non-zero secrecy capacity.

## 5.2 Artificial Noise Generation

Equations (2.1), (2.2) hold in this case, except that we have matrix channels  $\mathbf{H}_k$  and  $\mathbf{G}_k$ . The elements of noise vectors,  $\mathbf{n}_k$  and  $\mathbf{e}_k$  are i.i.d. AWGN samples. The transmitter transmits  $\mathbf{x}_k$  as in (3.1), where  $\mathbf{H}_k \mathbf{w}_k = \mathbf{0}$ , so that  $\mathbf{w}_k = \mathbf{Z}_k \mathbf{v}_k$ . However, in this case we choose  $\mathbf{Z}_k$  to be a *subset* of an orthonormal basis of the null space of  $\mathbf{H}_k$ . The receiver and the eavesdropper receive vector signals  $\mathbf{z}_k$  and  $\mathbf{y}_k$ , respectively. Based on (3.3), the eavesdropper  $E$  observes colored Gaussian noise with covariance  $\mathbf{K} = (\mathbf{G}_k \mathbf{Z}_k \mathbf{Z}_k^\dagger \mathbf{G}_k^\dagger) \sigma_v^2 + \mathbf{I} \sigma_e^2$ .

## 5.3 Secrecy Capacity

Now, the lower bound on secrecy capacity is given by [2, 15],

$$C_{sec}^a = I(\mathbf{Z}; \mathbf{S}) - I(\mathbf{Y}; \mathbf{S}) = \log |\mathbf{I} \sigma_n^2 + \mathbf{H}_k \mathbf{Q}_s \mathbf{H}_k^\dagger| - \log \left( \frac{|\mathbf{K} + \mathbf{G}_k \mathbf{Q}_s \mathbf{G}_k^\dagger|}{|\mathbf{K}|} \right), \quad (5.1)$$

where  $\mathbf{Q}_s = \mathbf{E}[\mathbf{s}_k \mathbf{s}_k^\dagger]$  and  $\mathbf{s}_k$  is complex Gaussian distributed. The minimum guaranteed secrecy capacity can be obtained by substituting  $\mathbf{K}$  with  $\mathbf{K}'$  in (5.1), where  $\mathbf{K}' = (\mathbf{G}_k \mathbf{Z}_k \mathbf{Z}_k^\dagger \mathbf{G}_k^\dagger) \sigma_v^2$ . We immediately note that in order to avoid the case  $|\mathbf{K}'| = 0$ , the rank of  $\mathbf{Z}_k$  (which lies in the null-space of  $\mathbf{H}_k$ ), must be at least  $N_E$ . Thus, the transmitter must use at least  $N_E$  dimensions for artificial noise. The remaining dimensions can be used for transmitting the information signal. Let  $N_{ND}$  and  $N_S$  denote the number of dimensions used for artificial noise and the information signal, respectively. The transmitter first chooses  $N_{ND}$ , where  $N_E \leq N_{ND} \leq N_T - 1$ . It then determines

$N_S = \min(N_R, N_T - N_{ND})$ . Then, it designs  $\mathbf{Q}_s$  and  $\mathbf{Z}_k$ , based on  $\mathbf{H}_k$ . Let the Singular Value Decomposition (SVD) of  $\mathbf{H}_k$  be given by  $\mathbf{H}_k = \mathbf{U}_k \mathbf{\Lambda}_k \mathbf{V}_k^\dagger$ . The transmitter chooses  $\mathbf{s}_k = \mathbf{V}_k \mathbf{r}_k$  and the receiver processes the received signal ( $\mathbf{z}_k$ ) by multiplying it by  $\mathbf{U}_k^\dagger$ . Then, the equivalent channel to the receiver becomes  $\tilde{\mathbf{z}}_k = \mathbf{\Lambda}_k \mathbf{r}_k + \tilde{\mathbf{n}}_k$ , where the components of  $\tilde{\mathbf{n}}_k$  are i.i.d. complex Gaussian with mean 0 and variance  $\sigma_n^2$ . To maximize the mutual information between the transmitter and the receiver, the transmitter chooses  $\mathbf{Q}_r = \mathbf{E}[\mathbf{r}_k \mathbf{r}_k^\dagger] = \text{diag}(\sigma_{r,1}^2, \dots, \sigma_{r,N_T}^2)$ , with  $\{\sigma_{r,i}^2\}$  chosen according to the waterfilling solution, corresponding to the  $N_S$  largest singular values of  $\mathbf{H}_k$ , with power constraint of  $P_{info}(\leq P_0)$ .  $\mathbf{Z}_k$  consists of  $N_{ND}$  columns of  $\mathbf{V}_k$ , which do not contribute to the signal space. Then, the minimum guaranteed secrecy capacity is given by,

$$C_{sec,mg}^a = \log |\mathbf{I}\sigma_n^2 + \mathbf{\Lambda}_k \mathbf{Q}_r \mathbf{\Lambda}_k^\dagger| - \log \left( |\mathbf{K}' + \mathbf{G}_k \mathbf{V}_k \mathbf{Q}_r \mathbf{V}_k^\dagger \mathbf{G}_k^\dagger| / |\mathbf{K}'| \right). \quad (5.2)$$

$C_{sec,mg}^a$  is a random variable because it is a function of random channel gains  $\mathbf{H}_k$  and  $\mathbf{G}_k$ . We assume that the total transmit power, given by  $\text{trace}(\mathbf{E}[\mathbf{x}_k \mathbf{x}_k^\dagger]) = \text{trace}(\mathbf{V}_k \mathbf{Q}_r \mathbf{V}_k^\dagger) + N_{ND} \sigma_v^2$ , is constrained to  $P_0$ . Now,  $P_{info} = \text{trace}(\mathbf{V}_k \mathbf{Q}_r \mathbf{V}_k^\dagger)$ ,  $N_{ND}$  and  $\sigma_v^2$  are chosen to maximize the average  $C_{sec,mg}^a$ ,

$$\overline{C_{sec,mg}^a} \doteq \max_{\text{tr}(\mathbf{V}_k \mathbf{Q}_r \mathbf{V}_k^\dagger) + N_{ND} \sigma_v^2 \leq P_0} \mathbf{E}[\log |\mathbf{I}\sigma_n^2 + \mathbf{\Lambda}_k \mathbf{Q}_r \mathbf{\Lambda}_k^\dagger| - \log \left( |\mathbf{K}' + \mathbf{G}_k \mathbf{V}_k \mathbf{Q}_r \mathbf{V}_k^\dagger \mathbf{G}_k^\dagger| / |\mathbf{K}'| \right)], \quad (5.3)$$

where the expectation is over the random gains  $\mathbf{H}_k$ ,  $\mathbf{G}_k$ .

## 5.4 Asymptotic Analysis

Analytical results on (usual) MIMO capacity are available for the asymptotic case of large number of antennas. We derive similar analytical results for MIMO secrecy capacity  $\overline{C_{sec,mg}^a}$ , for large number of antennas. (We also compare the two through numerical results, later in this section.) The presence of artificial noise significantly complicates the asymptotic analysis. Recall that the SVD of  $\mathbf{H}_k = \mathbf{U}_k \mathbf{\Lambda}_k \mathbf{V}_k^\dagger$ . The transmitter chooses  $N_{ND}$ , and then designs the covariance matrices for artificial noise ( $\mathbf{Q}_n$ ), and ( $\mathbf{Q}_s$ ),

$$\mathbf{Q}_n = \mathbf{V}_k \begin{pmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{I}_{N_{ND}} \sigma_v^2 \end{pmatrix} \mathbf{V}_k^\dagger, \quad \mathbf{Q}_s = \mathbf{V}_k \mathbf{Q}_r \mathbf{V}_k^\dagger = \mathbf{V}_k \begin{pmatrix} \mathbf{\Sigma}_s & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{pmatrix} \mathbf{V}_k^\dagger, \quad (5.4)$$

where  $\mathbf{\Sigma}_s$  is a  $N_S \times N_S$  diagonal matrix, obtained as the waterfilling solution over the  $N_S$  largest singular values of  $\mathbf{H}_k$ . Let  $\mathbf{V}_1$  denote the matrix with the first  $N_S$  columns of  $\mathbf{V}_k$ , and  $\mathbf{V}_2$  denote the

matrix with last  $N_{ND}$  columns of  $\mathbf{V}_k$ . Then,  $\mathbf{Q}_s = \mathbf{V}_1 \boldsymbol{\Sigma}_s \mathbf{V}_1^\dagger$ , and  $\mathbf{Z}_k = \mathbf{V}_2$ . We define  $\tilde{\mathbf{G}}_1 \doteq \mathbf{G} \mathbf{V}_1$ , and  $\tilde{\mathbf{G}}_2 \doteq \mathbf{G} \mathbf{V}_2$ . Note that due to the orthonormality of  $[\mathbf{V}_1, \mathbf{V}_2]$ ,  $\tilde{\mathbf{G}}_1$  and  $\tilde{\mathbf{G}}_2$  both have circularly symmetric i.i.d. complex Gaussian distributed elements. Eq. (5.3) can now be written as,

$$\overline{C_{sec,mg}^a} = \max_{tr(\mathbf{V}_1 \boldsymbol{\Sigma}_s \mathbf{V}_1^\dagger) + N_{ND} \sigma_v^2 \leq P_0} \mathbf{E}[\log |\mathbf{I} \sigma_n^2 + \boldsymbol{\Lambda}_k \mathbf{Q}_r \boldsymbol{\Lambda}_k^\dagger| - \log |\tilde{\mathbf{G}}_1 \boldsymbol{\Sigma}_s \tilde{\mathbf{G}}_1^\dagger + \tilde{\mathbf{G}}_2 \tilde{\mathbf{G}}_2^\dagger \sigma_v^2| + \log |\tilde{\mathbf{G}}_2 \tilde{\mathbf{G}}_2^\dagger \sigma_v^2|] \quad (5.5)$$

Now, the second term can be written as a function of  $\boldsymbol{\Sigma}_s$  as,  $S(\boldsymbol{\Sigma}_s) = \mathbf{E}[\log |\tilde{\mathbf{G}}_1 \boldsymbol{\Sigma}_s \tilde{\mathbf{G}}_1^\dagger + \tilde{\mathbf{G}}_2 \tilde{\mathbf{G}}_2^\dagger \sigma_v^2|]$ .

$$\text{Then, } S(\mathbf{P} \boldsymbol{\Sigma}_s \mathbf{P}^\dagger) = \mathbf{E}[\log |\tilde{\mathbf{G}}_1 \mathbf{P} \boldsymbol{\Sigma}_s \mathbf{P}^\dagger \tilde{\mathbf{G}}_1^\dagger + \tilde{\mathbf{G}}_2 \tilde{\mathbf{G}}_2^\dagger \sigma_v^2|] \stackrel{a}{=} S(\boldsymbol{\Sigma}_s), \quad (5.6)$$

where  $\mathbf{P}$  is a permutation matrix, and (a) holds because the elements of  $\tilde{\mathbf{G}}_1$  are circularly symmetric i.i.d. complex Gaussian random variables. Let  $N$  be the number of such permutation matrices.

Then,

$$\begin{aligned} S(\boldsymbol{\Sigma}_s) &= \frac{1}{N} \sum_{\mathbf{P}} \mathbf{E}[\log |\tilde{\mathbf{G}}_1 \mathbf{P} \boldsymbol{\Sigma}_s \mathbf{P}^\dagger \tilde{\mathbf{G}}_1^\dagger + \tilde{\mathbf{G}}_2 \tilde{\mathbf{G}}_2^\dagger \sigma_v^2|] \\ &\stackrel{b}{\leq} \mathbf{E}[\log |\tilde{\mathbf{G}}_1 \frac{1}{N} \sum_{\mathbf{P}} (\mathbf{P} \boldsymbol{\Sigma}_s \mathbf{P}^\dagger) \tilde{\mathbf{G}}_1^\dagger + \tilde{\mathbf{G}}_2 \tilde{\mathbf{G}}_2^\dagger \sigma_v^2|] \\ &= \mathbf{E}[\log |\tilde{\mathbf{G}}_1 \tilde{\mathbf{G}}_1^\dagger \sigma_p^2 + \tilde{\mathbf{G}}_2 \tilde{\mathbf{G}}_2^\dagger \sigma_v^2|] \\ &\stackrel{c}{\leq} \mathbf{E}_{\tilde{\mathbf{G}}_2} [\log |\mathbf{E}_{\tilde{\mathbf{G}}_1} [\tilde{\mathbf{G}}_1 \tilde{\mathbf{G}}_1^\dagger] \sigma_p^2 + \tilde{\mathbf{G}}_2 \tilde{\mathbf{G}}_2^\dagger \sigma_v^2|] \\ &= \mathbf{E}[\sum_i \log (P_{info} + \lambda_i \sigma_v^2)], \end{aligned} \quad (5.7)$$

where  $\sigma_p^2$  is the arithmetic mean of the diagonal elements of  $\boldsymbol{\Sigma}_s$ . (b) and (c) hold due to the concavity of log-determinant function. The expectation in the final equation is over  $\{\lambda_i\}$ , which are the eigenvalues of the Wishart matrix  $\tilde{\mathbf{G}}_2 \tilde{\mathbf{G}}_2^\dagger$ , which have the following distribution [17, 18].

$$p(\lambda) = \begin{cases} \frac{1}{\pi} \sqrt{\frac{\beta}{\lambda} - \frac{1}{4} \left(1 + \frac{\beta-1}{\lambda}\right)^2}, & \text{if } (\sqrt{\beta} - 1)^2 \leq \lambda \leq (\sqrt{\beta} + 1)^2 \\ 0, & \text{otherwise,} \end{cases} \quad (5.8)$$

where  $\beta = \max(N_E/(N_T - N_R), (N_T - N_R)/N_E)$ . Therefore,

$$\overline{C_{sec,mg}^a} \geq \overline{C_{sec,mg}^a}(LB) = \max_{tr(\mathbf{V}_1 \boldsymbol{\Sigma}_s \mathbf{V}_1^\dagger) + N_{ND} \sigma_v^2 \leq P_0} \mathbf{E}[\log |\mathbf{I} \sigma_n^2 + \boldsymbol{\Lambda}_k \mathbf{Q}_s \boldsymbol{\Lambda}_k^\dagger| - \sum_i \log \left( \frac{P_{info} + \lambda_i \sigma_v^2}{\lambda_i \sigma_v^2} \right)]. \quad (5.9)$$

Now, given the distribution of eigenvalues of a Wishart matrix (5.8), the lower bound obtained in (5.9), can be computed numerically. Note that for the first term in (5.9), we consider the  $N_S$

Figure 5.1: Minimum guaranteed average secrecy capacity: variation with  $N_R$  ( $N_T/N_R$  fixed)

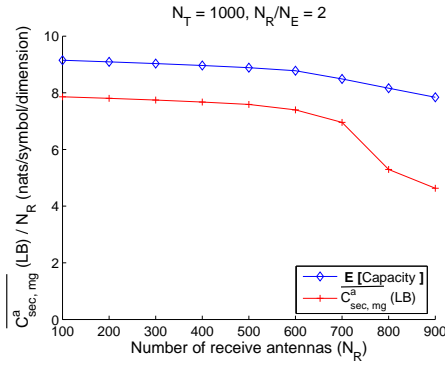

Figure 5.2: Minimum guaranteed average secrecy capacity: variation with  $N_R$  ( $N_T$  fixed)

largest eigenvalues, and hence, the distribution given in (5.8) has to be modified appropriately, as follows. In the limit of large number of antennas, the distribution of eigenvalues can be used as a histogram. Let  $\lambda_{th}$  be such that,  $\int_{\lambda_{th}}^{\infty} p(\lambda)d\lambda = N_S/N_R$ . Then, the distribution  $p$  of one of the largest  $N_S$  eigenvalues is given by,

$$p_{N_S}(\lambda) = \begin{cases} p(\lambda) \cdot N_R/N_S, & \lambda > \lambda_{th} \\ 0, & \text{otherwise.} \end{cases} \quad (5.10)$$

Fig. 5.1 shows the variation of  $\overline{C^a_{sec,mg}}(LB)$  (normalized w.r.t.  $N_R$ ) calculated using (5.9), as a function of  $N_R$ , while keeping the proportion of transmit, receive and eavesdropper antennas fixed. In particular, for this figure,  $N_T/N_R = 5$  and  $N_R/N_E = 1$ . Note that the variation of  $\overline{C^a_{sec,mg}}(LB)$  with  $N_R$  is similar to that of average capacity, in this case. Intuitively, a fixed proportion of the dimensions are used to produce artificial noise, and the number of dimensions used to transmit the signal also increases proportionally. Thus, the secrecy capacity increases with the number of receive

antennas. Fig. 5.2 shows the variation of (normalized)  $\overline{C_{sec,mg}^a}(LB)$  with  $N_R$ , with  $N_T (= 1000)$  and the ratio  $N_R/N_E (= 2)$  kept fixed. In this case, the (normalized) average capacity remains fairly constant, whereas the (normalized)  $\overline{C_{sec,mg}^a}(LB)$  reduces with increasing  $N_R$ , especially when  $N_R$  (and hence,  $N_E$ ) is large. Recall that at least  $N_E$  dimensions must be used for generating artificial noise to guarantee non zero average secrecy capacity. As  $N_E$  increases, the number of dimensions available for transmitting the signal reduces, reducing secrecy capacity. Similar trends can be observed in the simulation results, obtained for a small number of antennas, presented next.

## Chapter 6

# Simulation Results

### 6.1 Introduction

We use  $C_{sec,mg}$  to refer to both  $C_{sec,mg}^a$  and  $C_{sec,mg}^h$ , and  $C_{sec}$  to refer to both  $C_{sec}^a$  and  $C_{sec}^h$ , when the context is clear. We use similar notation for the average capacities. We compute the minimum guaranteed average secrecy capacity  $\overline{C_{sec,mg}}$ , which is compared with the average capacity of the transmitter-receiver link (without secrecy requirements), both computed under a power constraint of  $P_0$ . Further, given an outage capacity  $C_{outage}$ , we compute the outage probability  $Pr\{C_{sec,mg} < C_{outage}\}$ .  $\overline{C_{sec,mg}}$  and outage probability are computed using Monte Carlo simulations, using  $10^5$  and  $10^6$  iterations, respectively. In the multiple antenna scenario, it is assumed that the elements of  $\mathbf{H}_k$  and  $\mathbf{G}_k$  are statistically independent complex Gaussian random variables with  $\mathbf{E}[|h_{i,j}|^2] = \mathbf{E}[|g_{i,j}|^2] = 1$ . The channel gains are assumed to be i.i.d. complex Gaussian with  $\mathbf{E}[|\alpha_{XY}|^2] = 1$ . For computing the outage probabilities for a given number of transmit antennas (or number of amplifying relays) and total transmit power  $P_0$ , the combination of powers used is the one found by performing the optimization for  $\overline{C_{sec,mg}}$ .

### 6.2 Variation of Secrecy Capacity with Distance

Figures 6.1 and 6.2 show the variation of  $\overline{C_{sec}}$  with the distance between the transmitter and eavesdropper, for the multiple antenna and multiple amplifying relays scenario respectively. The

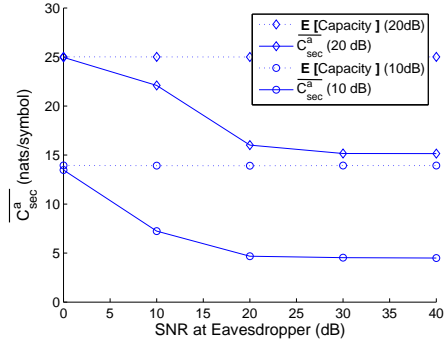

Figure 6.1: Minimum guaranteed average secrecy capacity: variation with distance (multiple antenna scenario)

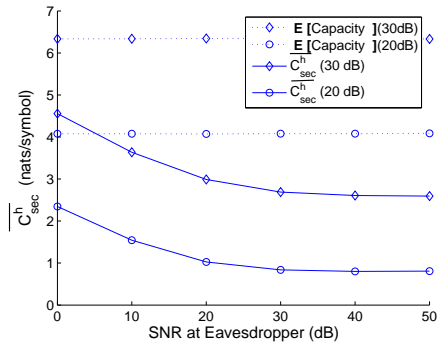

Figure 6.2: Minimum guaranteed average secrecy capacity: variation with distance (multiple amplifying relays scenario)

variation in eavesdropper's distance was modeled by varying the per-antenna SNR at the eavesdropper. The distance between the transmitter and receiver is assumed to remain constant. Figures 6.1 and 6.2 show that in both the scenarios, when the eavesdropper's distance from the transmitter is much larger than that of the receiver (i.e., when the eavesdropper's SNR is low),  $\overline{C}_{sec}$  is close to the average capacity, as expected. As the eavesdropper comes closer to the transmitter,  $\overline{C}_{sec}$  reduces. However, instead of becoming arbitrarily small, it ultimately approaches a floor. This is an important result, since, this guarantees a minimum average secrecy capacity, regardless of the eavesdropper's position. This effect is produced by the fact that artificial noise power can be made proportional to the signal power, which is not the case for AWGN.

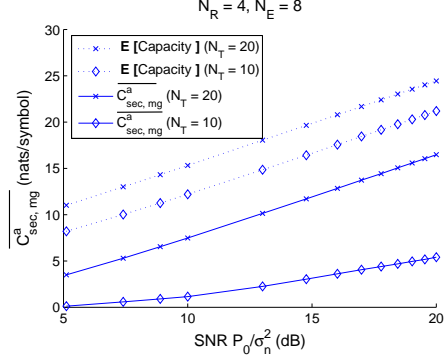

Figure 6.3: Minimum guaranteed average secrecy capacity: variation with  $P_0$  (multiple antenna scenario)

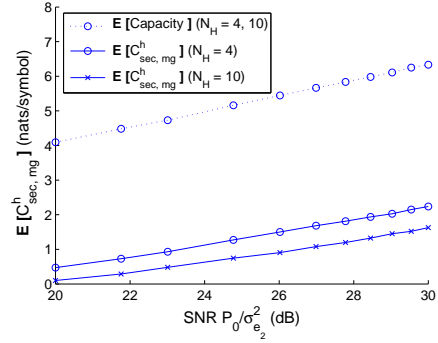

Figure 6.4: Minimum guaranteed average secrecy capacity: variation with  $P_0$  (multiple amplifying relays scenario)

### 6.3 Average Minimum Guaranteed Secrecy Capacity

Figures 6.3 and 6.4 show the variation of  $\overline{C_{sec,mg}}$  with the total available transmit power  $P_0$ . Note that in both the scenarios, the behavior of  $\overline{C_{sec,mg}}$  is similar to that of average capacity. Further, in the case of multiple antenna scenario,  $\overline{C_{sec,mg}}$  increases with  $N_T$ , just like average capacity. In the multiple amplifying relays scenario, on the other hand,  $\overline{C_{sec,mg}}$  reduces as  $N_H$  increases. The primary reason for this behavior is that, as  $N_H$  increases, the power available per node reduces. As opposed to the multiple antenna scenario, the relays are not under the direct control of the transmitter. Any cooperation between the transmitter and the relays (or among the relays themselves) requires multiple transmissions, which makes this scheme inefficient as  $N_H$

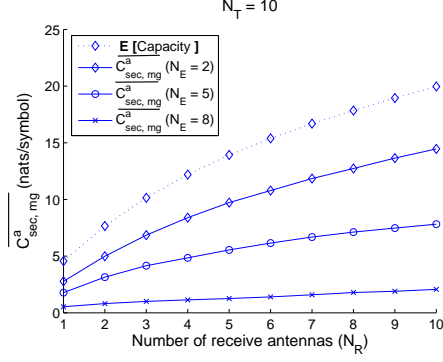

Figure 6.5: Minimum guaranteed average secrecy capacity: variation with  $N_E$  and  $N_R$

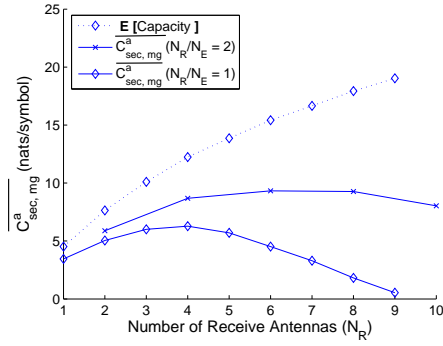

Figure 6.6: Minimum guaranteed average secrecy capacity: fixed ratio of  $N_E$  and  $N_R$

increases. However, we note that if there is more than one colluding eavesdropper, we will need to use more than one relay node to ensure secrecy.

All simulation results related to characterizing the behavior of  $\overline{C_{sec,mg}}$  show that, as expected, average capacity is an upper bound on  $\overline{C_{sec,mg}}$ . The difference between the two represents the loss in capacity because of the secrecy requirement. This loss occurs because of two reasons. Firstly, only part of the power  $P_{info}$  is used for the information signal while the rest of the power ( $P_0 - P_{info}$ ) is used for creating artificial noise. This reduces the mutual information  $I(\mathbf{Z}; \mathbf{S})$  (or  $I(Z; \tilde{R}_B)$ ) between the information signal and the signal received by the receiver. Secondly, the information that the eavesdropper gains about the information signal  $I(\mathbf{Y}; \mathbf{S})$  (or  $I(Z; \tilde{R}_{E,1}, \tilde{R}_{E,2})$ ) reduces secrecy capacity, based on (3.4), (4.10) or (5.1).

Fig. 6.5 shows that  $\overline{C_{sec,mg}}$  increases with  $N_R$ , similar to average capacity, when  $N_T$  ( $=10$ ) and  $N_E$  are fixed. An increase in  $N_R$  increases the average capacity, and also increases  $I(\mathbf{Z}; \mathbf{S})$ , as

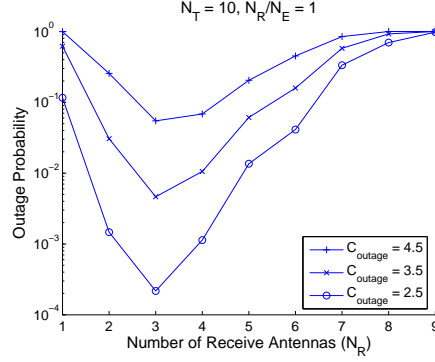

Figure 6.7: Outage probability: Multiple antenna scenario ( $N_R = N_E$ )

Figure 6.8: Outage Probability: Multiple antenna scenario ( $N_R = 2N_E$ )

the number of dimensions available for transmitting the information signal increase. Further, for a fixed  $N_R$ ,  $\overline{C_{sec,mg}}$  reduces with  $N_E$ , as expected. In Fig. 6.6, the ratio between  $N_R$  and  $N_E$  was kept constant, and  $N_T$  was kept fixed at 10. Two cases are considered, one with  $N_R = N_E$  and the other with  $N_R = 2N_E$ . Specifically, the case  $N_R = N_E$  suggests fairness, as both the eavesdropper and the receiver nodes are assumed to have similar capabilities. An interesting phenomenon is observed in both the cases; secrecy capacity attains a maximum at a value of  $N_R$  smaller than  $N_T$ , rather than at  $N_R = N_T$ , as would be the case with usual MIMO capacity. Intuitively, as  $N_E$  increases, the number of dimensions available for transmission of information signal becomes limited. Further, more power is required to produce artificial noise with the same noise power per dimension. It can be observed that the maximum occurs roughly when  $N_R + N_E \approx N_T$ , although we were unable to prove this conjecture analytically. These trends show that secrecy capacity does not behave like the usual MIMO capacity (without secrecy requirements).

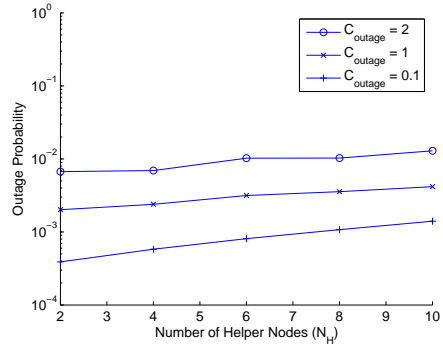

Figure 6.9: Outage probability: Multiple amplifying relays scenario

## 6.4 Outage Probability

Figures 6.7 and 6.8 show the variation of outage probability with  $N_R$ , with the ratio between  $N_R$  and  $N_E$  kept constant, for a fixed outage capacity. For all of these simulations, the SNR per antenna  $P_0/\sigma_n^2$  was fixed at 10 dB. Figures 6.7 and 6.8 show the same interesting phenomenon as described earlier for  $\overline{C_{sec,mg}}$ ; the outage probability is minimized at a value of  $N_R$  less than  $N_T$ . When  $N_R$  is small, the outage probability is limited mainly by the diversity available on the transmitter-receiver link, rather than by the secrecy requirement, since almost all the parallel channels of the eavesdropper are interference limited, with a high probability. As  $N_R$  increases, the number of parallel channels of the receiver increase resulting in high diversity, and hence, the outage probability reduces. However, for large  $N_R$  (and hence, large  $N_E$ ), at most  $N_T - N_E$  dimensions are available for transmission of information signal, again reducing the available diversity, and hence, increasing the outage probability. Fig. 6.9 shows the variation of outage probability with  $N_H$ , for the multiple amplifying relays scenario. As opposed to the multiple antenna scenario, the outage probabilities (for a fixed outage capacity) are fairly constant, as  $N_H$  is varied. The results suggest that as  $N_H$  increases, the limitation on the power available for information signal, is balanced out by the increase in the number of dimensions available for generating artificial noise.

## Chapter 7

# Conclusion

This report considered the problem of secret communication in a fading environment, in presence of passive eavesdroppers. The eavesdroppers were assumed to know the channel gains of all the channels (thus, secrecy was not dependent on the secrecy of channel gains) and they were allowed to collude. The report showed how secrecy can be achieved, by adding artificially generated noise to the information signal. It was shown that multiple antennas can be used to generate artificial noise, such that only the eavesdropper's channel is degraded. Further, even if the transmitter has only a single antenna, artificial noise can still be produced, with the help of amplifying relays. A necessary condition for using the method of artificial noise is that the total number of transmit antennas (including relays) must exceed the number of eavesdropper antennas. It was shown that MIMO secrecy capacity behaves differently from non-secret MIMO capacity, so that MIMO design is different under the secrecy requirement. It was shown that a non-zero rate for secret communication can be guaranteed, regardless of eavesdropper's position, i.e., even if the eavesdropper is much closer to the transmitter, compared to receiver. Further, it was shown that low outage probabilities of secrecy capacity can be achieved. Analytical results were presented for the multiple antenna scenario, in the regime of large number of antennas.
