Please submit as ONE PDF: [andrewID].pdf

1 Memory Scheduling [40+15 points]

Row-Buffer Conflicts. The following timing diagram shows the operation of a single DRAM channel and a single DRAM bank for two back-to-back reads that conflict in the row-buffer. Immediately after the bank has been busy for 10ns with a READ, data starts to be transferred over the data bus for 5ns.

- (a) Given a long sequence of back-to-back reads that always conflict in the row-buffer, what is the data throughput of the main memory system? Please state your answer in **gigabytes/second**.
- (b) To increase the data throughput, the main memory designer is considering adding more DRAM banks to the single DRAM channel. Given a long sequence of back-to-back reads to all banks that always conflict in the row-buffers, what is the minimum number of banks that is required to achieve the maximum data throughput of the main memory system?

Row-Buffer Hits. The following timing diagram shows the operation of the single DRAM channel and the single DRAM bank for four back-to-back reads that hit in the row-buffer. It is important to note that row-buffer hits to the same DRAM bank are pipelined: while each READ keeps the DRAM bank busy for 10ns, up to at most **half** of this latency (5ns) can be overlapped with another read that hits in the row-buffer. (Note that this is different from Lab 6 where we unrealistically assumed that row-buffer hits are non-pipelined.)

- (c) Given a long sequence of back-to-back reads that always hits in the row-buffer, what is the data throughput of the main memory system? Please state your answer in **gigabytes/second**.

- (d) When the maximum data throughput is achieved for a main memory system that has a single DRAM channel and a single DRAM bank, what is the bottleneck that prevents the data throughput from becoming even larger? **Circle** all that apply.

BANK COMMAND BUS ADDRESS BUS DATA BUS

Memory Scheduling Policies. The diagram below shows the memory controller's *request queue* at time 0. The shaded rectangles are read requests generated by thread T_0 , whereas the unshaded rectangles are read requests generated by thread T_1 . Within each rectangle, there is a pair of numbers that denotes the request's (*BankAddress*, *RowAddress*). Assume that the memory system has a **single** DRAM channel and **four** DRAM banks. Further assume the following.

- All the row-buffers are **closed** at time 0.
- Both threads start to stall at time 0 because of memory.
- A thread continues to stall until it receives the data for all of its requests.
- Neither thread generates more requests.

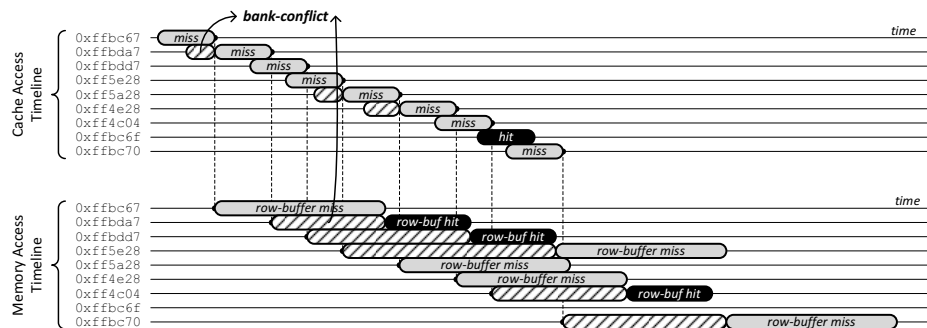

For extra credits (15 points), please make sure that you model contention in the banks as well as in all of the buses (address/command/data).

- (e) For the **FCFS** scheduling policy, calculate the memory stall time of T_0 and T_1 .
- (f) For the **FR-FCFS** scheduling policy, calculate the memory stall time of T_0 and T_1 .
- (g) For the **PAR-BS** scheduling policy, calculate the memory stall time of T_0 and T_1 . Assume that all eight requests are included in the same *batch*.

2 Banks [30 points]

A processor's memory hierarchy consists of a small SRAM L1-cache and a large DRAM main memory, both of which are banked. The processor has a 24-bit physical address space and does not support virtual memory (i.e., all addresses are physical addresses). An application has just started running on this processor. The following figure shows the timeline of memory references made by that application and how they are served in the L1-cache or main memory.

For example, the first memory reference made by the application is to byte-address `0xffbc67` (assume that all references are byte-sized reads to byte-addresses). However, the memory reference misses in the L1-cache (assume that the L1-cache is initially empty). Immediately afterwards, the application accesses main memory, where it experiences a row-buffer miss (initially, assume that all banks in main memory each have a row opened that will never be accessed by the application). Eventually, the cache block (and only that cache block) that contains the byte-address `0xffbc67` is fetched from memory into the cache.

Subsequent memory references may experience *bank-conflicts* in the L1-cache and/or main memory, if there is a previous reference still being served at that particular bank. Bank-conflicts are denoted as hatched shapes in the timeline.

The following table shows the address of the memory references made by the application in both hexadecimal and binary representations.

| | Hexadecimal | Binary |
|--|---------------------|-------------------------------|
| | <code>ffbc67</code> | 1111 1111 1011 1100 0110 0111 |
| | <code>ffbda7</code> | 1111 1111 1011 1101 1010 0111 |
| | <code>ffbdd7</code> | 1111 1111 1011 1101 1101 0111 |
| | <code>ff5e28</code> | 1111 1111 0101 1110 0010 1000 |
| | <code>ff5a28</code> | 1111 1111 0101 1010 0010 1000 |
| | <code>ff4e28</code> | 1111 1111 0100 1110 0010 1000 |
| | <code>ff4c04</code> | 1111 1111 0100 1100 0000 0100 |
| | <code>ffbc6f</code> | 1111 1111 1011 1100 0110 1111 |
| | <code>ffbc70</code> | 1111 1111 1011 1100 0111 0000 |

From the above timelines and the table, your job is to answer questions about the processor's cache and main memory organization. Here are some assumptions to help you along the way.

- Assumptions about the L1-cache
 - Block size: ? (Power of two, greater than two)
 - Associativity: ? (Power of two, greater than two)

- Total data-store size: ? (Power of two, greater than two)
- Number of banks: ? (Power of two, greater than two)
- Initially empty
- Assumptions about main memory
 - Number of channels: 1
 - Number of ranks per channel: 1
 - Number of banks per rank: ? (Power of two, greater than two)
 - Number of rows per bank: ? (Power of two, greater than two)
 - Number of cache-blocks per row: ? (Power of two, greater than two)
 - Contains the entire working set of the application
 - Initially, all banks have their 0^{th} row open, which is never accessed by the application

2.1 First, let's cover the basics

- (a) Caches and main memory are sub-divided into multiple banks in order to allow parallel access. What is an alternative way of allowing parallel access?
- (b) A cache that allows multiple cache misses to be outstanding to main memory at the same time is called what? (Two words or less. Hint: It's an adjective.)
- (c) While cache misses are outstanding to main memory, what is the structure that keeps bookkeeping information about the outstanding cache misses? This structure often augments the cache.
- (d) Which is larger, an SRAM cell or a DRAM cell?
- (e) What is the number of transistors and/or capacitors needed to implement each cell, including access transistor(s)?

2.2 Cache and memory organization

NOTE: For the following questions, assume that all offsets and indexes come from contiguous address bits.

- (a) What is the L1-cache's block size in bytes? Which bit positions in the 24-bit physical address correspond to the cache block offset? (The least-significant bit in the physical address has a bit position of 0.)
- (b) How many banks are there in the L1-cache? Which bit positions in the 24-bit physical address correspond to the L1-cache bank index? (The least-significant bit in the physical address has a bit position of 0.)
- (c) How many banks are there in main memory? Which bit positions in the 24-bit physical address correspond to the main memory bank index? (The least-significant bit in the physical address has a bit position of 0.)
- (d) What kind of interleaving is used to map physical addresses to main memory?
- (e) To fully support a 24-bit physical address space, how many rows must each main memory bank have? Which bit positions in the 24-bit physical address correspond to the main memory row index? (The least-significant bit in the physical address has a bit position of 0.)
- (f) Each cache block within a row is called a *column*. How many columns are there in a single row? Which bit positions in the 24-bit physical address correspond to the main memory column index? (The least-significant bit in the physical address has a bit position of 0.)

3 Refresh [40 points]

A memory system has four channels, and each channel has two ranks of DRAM chips. Each memory channel is controlled by a separate memory controller. Each rank of DRAM contains eight banks. A bank contains 32K rows. Each row in one bank is 8KB. The minimum retention time among all DRAM rows in the system is 64 ms. In order to ensure that no data is lost, every DRAM row is refreshed once per 64 ms. Every DRAM row refresh is initiated by a command from the memory controller which occupies the command bus on the associated memory channel for 5 ns and the associated bank for 40 ns. Let us consider a 1.024 second span of time.

We define *utilization* (of a resource such as a bus or a memory bank) as the fraction of total time for which a resource is occupied by a refresh command.

For each calculation in this section, you may leave your answer in *simplified* form in terms of powers of 2 and powers of 10.

- (a) How many refreshes are performed by the memory controllers during the 1.024 second period in total across all four memory channels?
- (b) What command bus utilization, across all memory channels, is directly caused by DRAM refreshes?
- (c) What data bus utilization, across all memory channels, is directly caused by DRAM refreshes?
- (d) What bank utilization (on average across all banks) is directly caused by DRAM refreshes?
- (e) The system designer wishes to reduce the overhead of DRAM refreshes in order to improve system performance and reduce the energy spent in DRAM. A key observation is that not all rows in the DRAM chips need to be refreshed every 64 ms. In fact, rows need to be refreshed only at the following intervals in this particular system:

| Required Refresh Rate | Number of Rows |
|-----------------------|----------------|
| 64 ms | 2^5 |
| 128 ms | 2^9 |
| 256 ms | all other rows |

Given this distribution, if all rows are refreshed only as frequently as required to maintain their data, how many refreshes are performed by the memory controllers during the 1.024 second period in total across all four memory channels?

What command bus utilization (as a fraction of total time) is caused by DRAM refreshes in this case?

- (f) What DRAM data bus utilization is caused by DRAM refreshes in this case?
- (g) What bank utilization (on average across all banks) is caused by DRAM refreshes in this case?
- (h) The system designer wants to achieve this reduction in refresh overhead by refreshing rows less frequently when they need less frequent refreshes. In order to implement this improvement, the system needs to track every row's required refresh rate. What is the minimum number of bits of storage required to track this information?
- (i) Assume that the system designer implements an approximate mechanism to reduce refresh rate using Bloom filters, as we discussed in class. One Bloom filter is used to represent the set of all rows which require a 64 ms refresh rate, and another Bloom filter is used to track rows which require a 128 ms refresh rate. The system designer modifies the memory controller's refresh logic so that on every potential refresh of a row (every 64 ms), it probes both Bloom filters. If either of the Bloom filter probes results in a "hit" for the row address, and if the row has not been refreshed in the most recent length of time for the refresh rate associated with that Bloom filter, then the row is refreshed. (If a row address hits in both Bloom filters, the more frequent refresh rate wins.) Any row that does not hit in either Bloom filter is refreshed at the default rate of once per 256 ms.

The false-positive rates for the two Bloom filters are as follows:

| Refresh Rate Bin | False Positive Rate |
|------------------|---------------------|
| 64 ms | 2^{-20} |
| 128 ms | 2^{-8} |

The distribution of required row refresh rates specified in part (e) still applies.

How many refreshes are performed by the memory controllers during the 1.024 second period in total across all four memory channels?

What command bus utilization results from this refresh scheme?

What data bus utilization results from this refresh scheme?

What bank utilization (on average across all banks) results from this refresh scheme?

4 Prefetching [40 points]

You and your colleague are tasked with designing the prefetcher of a machine your company is designing. The machine has a single core, L1 and L2 caches and a DRAM memory system.

We will examine different prefetcher designs and analyze the trade-offs involved.

- For all parts of this question, we want to compute prefetch accuracy, coverage and bandwidth overhead after the prefetcher is trained and is in steady state. Therefore, **exclude the first six requests from all computations.**
 - If there is a request already outstanding to a cache block, a new request for the same cache block will not be generated. The new request will be merged with the already outstanding request in the MSHRs.
- (a) You first design a stride prefetcher that observes the last three cache block requests. If there is a constant stride between the last three requests, it prefetches the next cache block using that stride.

You run an application that has the following access pattern to memory (these are cache block addresses):

A A+1 A+2 A+7 A+8 A+9 A+14 A+15 A+16 A+21 A+22 A+23 A+28 A+29 A+30...

Assume this pattern continues for a long time.

Compute the coverage of your stride prefetcher for this application.

Compute the accuracy of your stride prefetcher for this application.

- (b) Your colleague designs a new prefetcher that, on a cache block access, prefetches the next N cache blocks.

The coverage and accuracy of this prefetcher are 66.67% and 50% respectively for the above application. What is the value of N?

We define the bandwidth overhead of a prefetcher as

$$\frac{\text{Total number of cache block requests with the prefetcher}}{\text{Total number of cache block requests without the prefetcher}} \quad (1)$$

What is the bandwidth overhead of this next-N-block prefetcher for the above application?

- (c) Your colleague wants to improve the coverage of her next-N-block prefetcher further for the above application, but is willing to tolerate a bandwidth overhead of at most 2x.

Is this possible? **YES** **NO**

Why or why not?

- (d) What is the minimum value of N required to achieve a coverage of 100% for the above application? Remember that you should exclude the first six requests from your computations.

What is the bandwidth overhead at this value of N?

- (e) You are not happy with the large bandwidth overhead required to achieve a prefetch coverage of 100% with a next-N-block prefetcher. You aim to design a prefetcher that achieves a coverage of 100% with a 1x bandwidth overhead. Propose a prefetcher design that accomplishes this goal. Be concrete and clear.

5 Tiered-difficulty [40 points]

Recall from your required reading on Tiered-Latency DRAM that there is a near and far segment, each containing some number of rows. Assume a very simplified memory model where there is just one bank and there are two rows in the near segment and four rows in the far segment. The time to activate and precharge a row is 25ns in the near segment and 50ns in the far segment. The time from start of activation to reading data is 10ns in the near segment and 15ns in the far segment. All other timings are negligible for this problem. Given the following memory request stream, determine the optimal assignment (minimize average latency of requests) of rows in the near and far segment (assume a fixed mapping where rows cannot migrate, a closed-row policy, and the far segment is inclusive).

```
time 0ns: row 0 read
time 10ns: row 1 read
time 100ns: row 2 read
time 105ns: row 1 read
time 200ns: row 3 read
time 300ns: row 1 read
```

- What rows would you place in near segment? Hint: draw a timeline.
- What rows would you place in far segment?
- In 15 words or less, describe the insight in your mapping?
- Assume now that the mapping is dynamic. What are the tradeoffs of an exclusive design vs. an inclusive design? Name one advantage and one disadvantage for each.

Assume now that there are eight (8) rows in the near segment. Below is a plot showing the number of misses to the near segment for three applications (A, B, and C) when run alone with the specified number of rows allocated to the application in the near segment. This is similar to the plots you saw in your Utility-Based Cache Partitioning reading except for TL-DRAM instead of a cache. Determine the optimal static partitioning of the near segment when all three of these applications are run together on the system. In other words, how many rows would you allocate for each application? Hint: this should sum to eight. Optimal for this problem is defined as minimizing total misses across all applications.

- How many near segment rows would you allocate to A?
- How many near segment rows would you allocate to B?
- How many near segment rows would you allocate to C?

6 Memory System (Optional)

A machine with a 4 GB DRAM main memory system has 4 channels, 1 rank per channel and 4 banks per rank. The cache block size is 64 bytes.

(a) You are given the following byte addresses and the channel and bank to which they are mapped:

Byte: 0x0000 \Rightarrow Channel 0, Bank 0
Byte: 0x0100 \Rightarrow Channel 0, Bank 0
Byte: 0x0200 \Rightarrow Channel 0, Bank 0
Byte: 0x0400 \Rightarrow Channel 1, Bank 0
Byte: 0x0800 \Rightarrow Channel 2, Bank 0
Byte: 0x0C00 \Rightarrow Channel 3, Bank 0
Byte: 0x1000 \Rightarrow Channel 0, Bank 1
Byte: 0x2000 \Rightarrow Channel 0, Bank 2
Byte: 0x3000 \Rightarrow Channel 0, Bank 3

Determine which bits of the address are used for each of the following address components. Assume row bits are higher order than column bits:

- Byte on bus
Addr [2 : 0]
- Channel bits (channel bits are contiguous)
Addr [_____ : _____]
- Bank bits (bank bits are contiguous)
Addr [_____ : _____]
- Column bits (column bits are contiguous)
Addr [_____ : _____]
- Row bits (row bits are contiguous)
Addr [_____ : _____]

(b) Two applications App 1 and App 2 share this memory system (using the address mapping scheme you determined in part (a)). The memory scheduling policy employed is FR-FCFS. The following requests are queued at the memory controller request buffer at time t . Assume the first request (A) is the oldest and the last one (A + 15) is the youngest.

A B A + 1 A + 2 A + 3 B + 10 A + 4 B + 12 A + 5 A + 6 A + 7
A + 8 A + 9 A + 10 A + 11 A + 12 A + 13 A + 14 A + 15

These are cache block addresses, not byte addresses. Note that requests to A + x are from App 1, while requests to B + x are from App 2. Addresses A and B are row-aligned (i.e., they are at the start of a row) and are at the same bank but are in different rows.

Assuming row-buffer hits take T time units to service and row-buffer conflicts/misses take 2T time units to service, what is the slowdown (compared to when run alone on the same system) of i) App 1? ii) App 2?

- (c) Which application slows down more? Why?
- (d) In class, we discussed memory channel partitioning and memory request scheduling as two solutions to mitigate interference and application slowdowns in multicore systems. Propose another solution to reduce the slowdown of the more-slowed-down application, *without* increasing the slowdown of the other application? Be concrete.
